Abstract Malaria is a parasitic disease that is widespread in the world and endemic to intertropical zones. According to World Health Organization, Africa is the most affected by malaria, especially in its sub-Saharan zone. Important work has been done on malaria, however, there are some drug resistance developed by certain strains of *plasmodium*. This work aim to propose a model of antimalarial 2D-pharmacophore based on a theoretical study of the relation between the electronic structure of a series of molecules derived from chalcone and the antiplasmodial activity in vitro against the *pf*3D7 strain. This QSAR study was done according to the Klopman-Peradejordi-Gômez technique (KPG). Using the Gaussian program, the DFT / B3LYP method in the 6-31G database (d, p), the optimization of the geometries of the molecules was done. After a multiple linear regression using Statistica software, an equation expressing log (IC₅₀) as a function of eight molecular reactivity indices was obtained. Analysis of the results made it possible to propose a 2D pharmacophore; this will enable us to propose more reactive antimalarial molecules. The process seems to be charge and orbital-controlled.

Keywords Chalcone; antimalarial activity; pf3D7 strain; QSAR, DFT, KPG approach

1. Introduction

Malaria is currently recognized as one of the intercontinental tropical infectious diseases that affects our populations [1]. With more or less different clinical effects, malaria is caused by parasites of the genus *Plasmodium* [2]. Although four *Plasmodium* species (*P. falciparum*, *P. vivax*, P. ovale, and *P. malariae*) cause human malaria, *Plasmodiumfalciparum* is the most virulent. The infections caused by *Plasmodium falciparum* is prevalent in the major parts of Africa, sub-Saharan Africa and East Asian countries [3], whose strain *pf*3D7 [4] was the subject of our study. Parasites are transmitted to humans by the bite of a vector; it is the infested Anopheles female mosquito, which usually stings in the early evening and in the deep night [5]. Through its saliva which plays a sedative role during its blood meal, the infested female Anopheles ingests in the blood of a receptive subject; parasites of the genus *Plasmodium*pursue part of their cycle evolutionary in human blood [1]. These parasites haematozoa developing and subsequently trigger various clinical effects of malaria (high fever, migraines, chills and anemia) [6]. In the light of the different antimalarial treatments against malaria [7-9], there are also some plasmodial strains that develop bio-resistant factors and become more and more chemo-resistant [10-12]. Various malaria vaccines are in the experimental phase [13-15]. A large list of drugs such as Quinine, Primaquine, chloroquine, mefloquine, halofantrine, lumefantrine, piperaquine, proguanil and artemisinin derivatives (artemether, artemminol, dihydroartemisinproguanil) [4] are used to treat malaria. But each of these drugs has one or more problems such as

inefficiency or is a source of toxicity or resistance during treatments of malaria phases. Previous work has shown that chalcone compounds have interesting antibacterial, antileishmanial [16-19] and especially antiplasmodial properties, [20-24]. These properties are expressed through the IC₅₀ values of each molecule. By the theoretical chemistry combined with the Quantitative Strutural Analysis Relationship (QSAR) [25-26] we present a study of the relationship between the electronic structure and the antiplasmodial activity of chalcones on malaria.

2. Methods, materials and calculations

2.1 Method and material

The method used to determine the quantitative relationship between structure-activity is the Klopman-Peradejordi-Gómez (KPG) method. This methodology used here to find the relation between the electronic structure and the inhibition constant is widely discussed and applied in several works, we present a summary below [27-30]. The median inhibition constant IC₅₀ can be expressed as a linear relation of the form:

$$\log(IC_{50}) = a + \sum_{j} \left[e_{j}Q_{j} + f_{j}S_{j}^{E} + s_{j}S_{j}^{N} \right] + \sum_{j} \sum_{m} \left[h_{j}(m)F_{j}(m) + x_{j}(m)S_{j}^{E}(m) \right] \\ + \sum_{j} \sum_{m} \left[r_{j}(m')F_{j}(m') + t_{j}(m')S_{j}^{N}(m') \right] + \sum_{j} \left[g_{j}\mu_{j} + k_{j}\eta_{j} + o_{j}\omega_{j} + z_{j}\zeta_{j} + w_{j}Q_{j}^{\max} \right] + \sum_{k=1}^{U} O_{k}$$
(1)

 S_{j}^{E} and S_{j}^{N} are, respectively, the total atomic electrophilic and nucleophilic superdelocalizabilities of atom j.

 $F_{j,m}(F_{j,m'})$ is the Fukui index of the occupied (vacant) MO m(m') located on atom j [31]

 $S^{\scriptscriptstyle E}_{\,i}(m)$ is the atomic electrophilic superdelocalizability of MO m on atom j,

 $S^{\rm N}_{\,\rm i}(m)$ is the atomic nucleophilic superdelocalizability of MO m' on $\,$ atom j

The total atomic electrophilic superdelocalizability of atom j corresponds to the sum over occupied MOs of the $S_j^E(m)$'s and the total atomic nucleophilic superdelocalizability of atom j is the sum over vacant MOs of $S_j^N(m)$'s[27].

 μ_i is the local atomic electronic chemical potential of atom j, η_i is the local atomic hardness of atom j,

 ω_i is the local atomic electrophilicity of atom j,

 ζ_{i} is the local atomic softness of atom j, and

 Q_i^{max} is the maximum amount of electronic charge that atom j may accept from another site [27]

 O_k 's are the orientational parameters of the substituents[32].

Throughout this paper $HOMO_j^*$ refers to the highest occupied molecular orbital localized on atom j and $LUMO_j^*$ to the lowest empty MO localized on atom j. They are called the local atomic frontier MOs.

The application of this method (equation (1)) has yielded exceptional results for a large number of systems diversity: Drug-Receptor in several studies [33-38].

For the application of this method, a series of twenty-four molecules [39] are selected from chalcone derivatives whose basic structure is the main compound is (E) 1,3-diparaphenylprop-2-en-1 one, whose experimental antiplasmodial activities are known. The structures of these compounds are summarized in the model of Figure 1 below. Table 1 summarizes the values of the experimental median inhibitory concentrations of each molecule: these values come from the literature [39]. These tests were performed on the blood form of plasmodium pf3D7 strain.

2.2 Model, calculations and applications

The Gaussian03 package of software [40] was used to optimize the geometry of all molecules in their neutral form. The calculations were performed within the Density Functional Theory (DFT) at the B3LYP/6-31G(d,p) level. The D-Cent-QSAR software [41] was used to calculated the local atomic reactivity indices from the single point results of Gaussian03. All electron populations lesser than or equal to 0.01e are considered null [42]. The orientational parameters of the substituents are calculated in the usual manner [43-44]. We used the concept of common skeleton defined as a set of atoms common to all the molecules analyzed. We hypothesize that the variation of the numerical values of the local atomic reactivity indices (LARIs) of the atoms of this common skeleton accounts for almost all the variation of the biological activity. The numbering of the atoms of the common is shown in Fig. 2.

As the number of LARIs involved is greater that the number of molecules, the solving of the linear systems of equations is not possible. For this reason we employed the technique of linear multiple regression analysis (LMRA) to determine the atoms that are directly involved in the variation of the biological activity. The data matrix contains

 $log (IC_{50})$ as a dependent variable, and the local atomic reactivity indices of all the atoms of the common skeleton as independent variables. The Statistica software was used to perform LMRA studies [45].

3. Results

The best statistically significant equation obtained is:

$$log(IC_{50}) = 8.17 + 1.63\mu_9 - 0.04S_8^N (LUMO + 2) * + 0.86F_{11}(HOMO - 1) * + 1.03F_{12}(LUMO + 1) * - 0.003S_{12}^N (LUMO + 1) * - 0.66F_{14}(HOMO - 2) * - 2.03F_5(HOMO - 1) * + 0.49Q_{13}$$

With statistical parameters (n = 24, (R = 0.99, R² = 0.98, R²adj = 0.97, F (8.15) = 94.89, (p-Value <0.000001), a standard error estimated at 0.14 and absence of outliers outside the $\pm 2\sigma$ limit.) The following indices of reactivity have been grouped into four different types:

 μ_9 is the local atomic electronic chemical potential of atom 9,

 $S_8^N (LUMO + 2)^*$ is the atomic nucleophilic superdelocalizability of third lowest vacant MO on atom 8;

 $F_{11}(HOMO-1)$ * is the Fukui index of the second highest occupied MO located on atom 11;

 $F_{12}(LUMO+1)$ * is the Fukui index of the second lowest vacant MO located on atom 12;

 $S_{12}^{N}(LUMO+1)$ * is the atomic nucleophilic superdelocalizability of second lowest vacant MO on atom 12;

 $F_{14}(HOMO-2)^*$ is the Fukui index of the third highest occupied MO located on atom 14;

 $F_5(HOMO-1)^*$ is the Fukui index of the second highest occupied MO located on atom 5;

 Q_{13} is the charge of atom 13.

The values of the beta coefficients, the t-tests (Tab II) obtained are very significant for the variables of equation (2). The highest internal correlation value is 0.41 (TabIII), is observed between the independent variables $S_{12}^N(LUMO+1)^*$ and $F_{12}(LUMO+1)^*$. Figure 3 shows the curve showing a good relationship between the log (IC₅₀) values observed and those calculated. Table IV shows the Local Molecular Orbitals of atom 5, 8, 11, 12 and 14 (see Fig. 3). Nomenclature: Molecule (HOMO) / (HOMO-2)* (HOMO-1)* (HOMO)* - (LUMO)* (LUMO+1)* (LUMO+2)*. The number corresponding of the HOMO of each molecule is in bracket, and for each atom we have the third local HOMO* and the third local LUMO*.

The statistical parameters associated with equation (2) show that this equation is statistically significant and involves the variation of eight local indices of atomic reactivity along the skeleton common to 97% of the log variation (IC_{50}).

4. Discussion

The results obtained indicate that a good antiplasmodial activity of these 24 chalcone derivatives is related to the variation of the different numerical values of all eight local indices of atomic reactivity along the common skeleton. This result is very good considering the approximations made to build the model.

From the comparison of the values of the beta coefficients it follows the importance in descending order of the following variables: $F_5(HOMO - 1)^* > \mu_9 > F_{12}(LUMO + 1)^* >$

 $F_{11}(HOMO - 1) *> F_{14}(HOMO - 2) *> Q_{13} > S_8^N (LUMO + 2) *> S_{12}^N (LUMO + 1) *$

The process seems to be orbital and charge-controlled because the indices on the electron population or/and the energies of MOs and the charge.

Variable by Variable Analysis indicates that a good antiplasmodial activity is associated with the high negative value of μ_9 , the high positive value of $S_8^N(LUMO+2)^*$, $F_{14}(HOMO-2)^*$, $F_5(HOMO-1)^*$, the low positive value of $F_{11}(HOMO-1)^*$, $F_{12}(LUMO+1)^*$, $S_{12}^N(LUMO+1)^*$ and the high negative value of Q_{13} . All the orbitals implicated on the process are π nature (Tab IV).

Atom 9 is a carbon atom of the carbonyl group, the high negative value of μ_9 indicates that atom 9 act as an electroacceptor site that must interact with an electron rich center of the receptor.

Atom 8 is a carbon atom, the high positive value of $S_8^N (LUMO + 2)^*$ should be obtained whether by raising the Fukui index on $(LUMO+2)_{15}^*$ or by lowering the $(LUMO+2)_{15}^*$ energy. In the two cases, the three lowest LUMO should be more reactive. So atom 8 interacts with an electron rich center through its π empty orbitals.

Atom 11 is a carbon atom of the phenyl that links to the carbonyl group. The presence of $(HOMO-1)_{11}^*$ implies that $(HOMO)_{11}^*$ participates to the process. The low positive value of $F_{11}(HOMO-1)^*$ indicates that atom 11 interacts with an electron rich center through its highest occupied orbitals. This interaction could be π - π , or π - σ kind.

Atom 12 is a carbon atom of the phenyl that links to the carbonyl group. The low positive value of $F_{12}(LUMO+1)^*$ indicates that atom 12 interacts with an electron-deficient center such as a cation. This is in perfect agreement with the low value of $S_{12}^N(LUMO+1)^*$.

Atom 14 is a carbon atom of the phenyl that links to the carbonyl group. The low positive value of $F_{14}(HOMO-2)^*$ indicates that atom 14 interacts with an electron rich center.

Atom 5 is a carbon of one phenyl ring. The high positive value of $F_5(HOMO-1)^*$ indicate that atom 5 should interacts with an electron-deficient center.

Atom 13 is a carbon atom of the phenyl that links to the carbonyl group. The positive sign of the coefficient of the net charge Q_{13} imposes us the choice of a high negative value of this index on the carbon atom 13 and induces the necessity that it interacts with a positive site.

All these suggestions are presented in the partial 2D inhibition pharmacophore on Figure 5.

Figure 4: Partial 2D-Pharmacore for antiplasmodial activity of chalcone derivatives on plasmodium falciparum strain pf3D7

4. Conclusion

We obtained a statistically significant relationship between the variation of the antiplasmodial activities of some chalcone derivatives and the variation of the numerical values of a set of local atomic reactivity indices. We propose a model of 2D-pharmacophore. It follows that the choice, the nature, and the position of a substitute to be grafted on the electronic structure of the skeleton are decisive for obtaining good antipasmodial activity. Thus the regression equation obtained could serve as a tool for predicting the antiplasmodial activity of other chalcones.

Acknowledgments

We thank Juan S. Gomez-Jeria, who accept to perform one part of the calculation on the computers of the Quantum PharmacologyUnit of the University of Chile.
